PAGE 1: INTRODUCTION & CLINICAL SIGNIFICANCE OF LIVER DISEASE PREDICTION

1.1 Background on Chronic Liver Diseases (CLD)

Chronic Liver Disease (CLD) represents a major global health challenge, causing approximately 2 million deaths per year worldwide. CLD is characterized by a gradual destruction of liver tissue over time, leading to progressive scarring (cirrhosis), liver failure, or hepatocellular carcinoma (liver cancer). The primary aetiologies of liver disease include chronic hepatitis B and C virus infections, non-alcoholic fatty liver disease (NAFLD) — increasingly referred to as metabolic dysfunction-associated steatotic liver disease (MASLD) — alcohol-associated liver disease (ALD), autoimmune disorders, and genetic conditions (e.g., hemochromatosis, Wilson's disease). The liver is a vital organ responsible for over 500 essential functions, including:

- * Metabolism: Processing carbohydrates, proteins, and fats.
- * Detoxification: Filtering toxins, drugs, and metabolic byproducts from the blood.
- * Synthesis: Producing crucial proteins like albumin and blood-clotting factors.
- * Storage: Storing glycogen, vitamins, and minerals.

When the liver is chronically injured, it undergoes continuous inflammation and cellular repair. Over time, this process leads to fibrotic tissue deposition. If left unchecked, the functional liver parenchyma is replaced by non-functional scar tissue, culminating in cirrhosis.

1.2 The Clinical Challenge of Early Diagnosis

A defining characteristic of chronic liver disease is its asymptomatic nature during the early stages. The liver possesses an extraordinary regenerative capacity and a large functional reserve. Consequently, patients often remain completely asymptomatic or present with non-specific symptoms (such as fatigue, mild abdominal discomfort, or nausea) until 70% to 80% of the liver tissue is already damaged. By the time clinical signs of advanced liver failure manifest — such as jaundice (yellowing of skin and eyes), ascites (fluid accumulation in the abdomen), hepatic encephalopathy (cognitive impairment due to circulating toxins), or variceal bleeding — the disease is frequently irreversible. In these advanced stages, treatment options are limited, highly expensive, and often restricted to liver transplantation, which is constrained by severe donor shortages. Consequently, early-stage detection is paramount. Standard diagnostic pathways rely on a combination of:

1. Liver Function Tests (LFTs): Panel blood tests measuring enzymes and proteins.
2. Imaging Studies: Ultrasound, Computed Tomography (CT), Magnetic Resonance Imaging (MRI), or transient elastography (FibroScan) to assess stiffness.
3. Liver Biopsy: The gold standard, which is highly invasive, carries risks of bleeding and pain, and is subject to sampling errors.

1.3 Role of Artificial Intelligence and Machine Learning

Traditional diagnostic methods often fail to catch early-stage liver disease due to the complex, non-linear relationships among clinical markers. A single elevated liver enzyme might not trigger a clinical alarm, but when analyzed in conjunction with age, gender, bilirubin, and protein levels, it can reveal a distinct pattern of early hepatic decline. Artificial Intelligence (AI) and Machine Learning (ML) present a powerful paradigm shift in this domain. By training mathematical classifiers on large, diverse cohorts of patient data, ML systems can:

- * Identify Subclinical Patterns: Recognize multi-variable biomarker signatures that escape manual clinical observation.
- * Enable Non-Invasive Screening: Utilize cheap, routine blood test parameters (like those in LFTs) to predict liver disease, eliminating the immediate need for expensive imaging or invasive biopsies.
- * Automate Risk Stratification: Instantly flag high-risk patients in primary care settings, directing them to hepatologists for early intervention.

1.4 Objectives of the Liver Disease Prediction System

The primary goal of the proposed system is to bridge the gap between academic research and clinical utility. Specifically, the system aims to:

1. Develop High-Accuracy Classifiers: Implement and optimize state-of-the-art machine learning models (such as Random Forest and XGBoost) to classify patients as "healthy" or "liver disease patients".
 2. Solve Data Challenges: Implement robust preprocessing pipelines to handle missing data, reduce feature noise, and overcome the severe class imbalance inherent in medical datasets.
 3. Provide Explainability: Integrate Explainable AI (XAI) models like SHAP to convert the "black-box" predictions of ensemble models into clear, visual feature-contribution plots that clinicians can interpret and trust.
 4. Deliver a Modern, Accessible Interface: Build a responsive, responsive dashboard that allows health professionals to input clinical test scores and receive an instant risk assessment.
-

PAGE 2: RESEARCH METHODOLOGY & LITERATURE SEARCH STRATEGY

2.1 Information Sources & Search Platforms

To establish a rigorous, evidence-based foundation for the Liver Disease Prediction System, a systematic literature search was conducted across multiple prominent databases:

- * Google Scholar: Utilized to capture a broad spectrum of citations, preprint papers, and cross-disciplinary research at the intersection of computer science and medicine.
- * ResearchGate: Consulted to access full-text preprints, conference proceedings, and direct communications from active researchers working on medical informatics.
- * PubMed / PMC (PubMed Central): Used to retrieve high-impact, peer-reviewed clinical studies to ensure that the machine learning models discussed align with physiological and clinical realities.
- * IEEE Xplore: Accessed to investigate technical articles describing algorithmic improvements, voting ensemble structures, and feature engineering techniques.

2.2 Search Queries and Keywords

The search queries were carefully structured using Boolean operators (AND, OR) and exact phrase matching to ensure high relevance and minimize noise. The following primary search strings were executed:

- ("liver disease prediction" OR "liver disease classification") AND ("machine learning" OR "ensemble learning") AND ("Indian Liver Patient Dataset" OR "ILPD")
- ("liver disease diagnosis" OR "hepatology AI") AND ("Random Forest" OR "XGBoost" OR "SVM") AND ("accuracy" OR "F1-score" OR "AUC-ROC")
- ("Explainable AI" OR "SHAP" OR "LIME") AND ("liver disease prediction") AND ("clinical decision support")
- ("demographic-aware" OR "gender-specific") AND ("liver disease prediction")

Visual Search Strategy Diagram:

2.3 Study Selection Criteria

To ensure the technical blueprint is based on state-of-the-art and reproducible methodologies, papers were filtered using strict inclusion and exclusion criteria:

Inclusion Criteria:

- Papers published or prepublished between 2023 and 2026 to capture modern advancements in ensemble modelling and Explainable AI.
- Studies that utilized benchmark datasets (such as the Indian Liver Patient Dataset from UCI or the BUPA Liver Disorders dataset) or documented large-scale clinical cohorts.
- Research that explicitly reports standard performance evaluation metrics: Accuracy, Sensitivity (Recall), Specificity, F1-Score, and Area Under the Receiver Operating Characteristic (AUC-ROC) curve.
- Studies that provide a clear methodology for data preprocessing, hyperparameter optimization, and handling class imbalances.

Exclusion Criteria:

- Dissertations or papers lacking peer-review validation (except highly cited preprints on ResearchGate).
- Studies utilizing imaging data (e.g., MRI/CT scans) exclusively, as the target system is designed to predict liver disease based on cheap, non-invasive biochemical blood panels.
- Papers with incomplete methodologies that do not explain their model training process or lack cross-validation validation.

2.4 Synthesis of Selected Literature

The literature search yielded a wealth of technical and clinical insights. The consolidated findings indicate that:

- * **Algorithmic Trend:** Single classifiers (like Naive Bayes or simple Logistic Regression) are no longer state-of-the-art. Modern frameworks rely on ensemble methods (e.g., Random Forests, XGBoost, and LightGBM) or voting/stacking combinations that combine tree-based decisions.
 - * **Preprocessing Priority:** The performance bottleneck in clinical ML is rarely the algorithm itself; rather, it is data quality. Successful papers dedicate substantial focus to missing value imputation, outlier handling, and addressing severe class imbalance (where diseased cases outnumber healthy records in benchmark datasets).
 - * **Demographic Sensitivity:** Emerging research (2025–2026) highlights the importance of demographic-aware models, showing that liver enzyme ranges vary naturally with age and biological sex, and models that stratify patients accordingly achieve significantly higher precision.
-

PAGE 3: DEEP DIVE: TRADITIONAL MACHINE LEARNING CLASSIFIERS

To appreciate the necessity of modern ensemble architectures, it is crucial to analyze the mathematical underpinnings and clinical limitations of traditional "single-classifier" machine learning models.

TRADITIONAL CLASSIFIERS	LIMITATIONS
+-----+	+-----+
- Support Vector Machines (SVM)	-> - High sensitivity to outliers
- Logistic Regression (LR)	-> - Poor modeling of non-linearities
- K-Nearest Neighbors (KNN)	-> - Curse of dimensionality
- Naive Bayes (NB)	-> - High bias / Low variance
+-----+	+-----+

3.1 Support Vector Machines (SVM)

Support Vector Machines are supervised learning models that find the optimal hyperplane maximizing the margin between classes. In a liver disease prediction context, the clinical features (Bilirubin, AST, ALT, etc.) form an N-dimensional space. SVM attempts to draw a boundary that separates "diseased" from "healthy" patients.

Hyperplane: $w^T x + b = 0$

Kernel Trick:

Since clinical biomarker interactions are rarely linear, researchers employ the Radial Basis Function (RBF) kernel to project the data into a higher-dimensional space where linear separation becomes possible:

$$K(x_i, x_j) = \exp(-\gamma \|x_i - x_j\|^2)$$

Clinical Limitation:

While SVM is highly effective in high-dimensional spaces, it is highly sensitive to the scale of features (requiring strict Z-score standardization) and exhibits poor computational efficiency on larger datasets. Furthermore, selecting the optimal hyperparameters (regularization parameter C and kernel coefficient γ) requires exhaustive search.

3.2 Logistic Regression (LR)

Logistic Regression models the probability of a binary outcome (liver disease vs. healthy) using the sigmoid function:

$$P(Y=1 | X) = 1 / (1 + e^{-(wTx + b)})$$

Clinical Limitation:

Logistic Regression serves as an excellent baseline due to its simplicity and high interpretability (the coefficients directly represent the log-odds of risk). However, it assumes a linear relationship between the log-odds of the outcome and the predictor variables. In liver disease, enzyme elevations (e.g., AST/ALT) often exhibit threshold-based, highly non-linear behaviors, which Logistic Regression fails to model accurately without manual polynomial feature engineering.

3.3 K-Nearest Neighbors (KNN)

KNN is a non-parametric, instance-based algorithm that classifies a patient based on the majority vote of their k nearest neighbors in the feature space, calculated using distance metrics such as Euclidean distance:

$$d(x, y) = \sqrt{(\sum_{i=1}^n (x_i - y_i)^2)}$$

Clinical Limitation:

KNN is heavily affected by the "curse of dimensionality" and is sensitive to irrelevant or unnormalized features. In liver patient datasets, the presence of noisy features or highly correlated attributes (such as AST and ALT) distorts the distance calculations, leading to poor specificity and high false-positive rates.

3.4 Naive Bayes (NB)

Naive Bayes classifiers are based on Bayes' Theorem, with the "naive" assumption of conditional independence between every pair of features given the class label:

$$P(C | x_1, \dots, x_n) \propto P(C) \prod_{i=1}^n P(x_i | C)$$

3.5 Decision Trees (DT)

Decision Trees split the data recursively based on feature thresholds that maximize information gain or minimize Gini impurity:

$$\text{Gini}(D) = 1 - \sum_{i=1}^c p_i^2$$

Clinical Limitation:

Although Decision Trees mirror clinical decision-making flowcharts, a single decision tree is highly prone to overfitting. Small variations in the patient training dataset can result in a completely different tree structure, making the model unstable and unreliable for clinical diagnostic settings.

PAGE 4: ADVANCED TECHNIQUES: ENSEMBLE & DEEP LEARNING ARCHITECTURES

To overcome the high bias or high variance of traditional classifiers, modern research focuses on ensemble paradigms and neural network structures.

4.1 Random Forest (RF) and Bagging

Random Forest is a bagging (bootstrap aggregating) ensemble of independent Decision Trees.

Each tree is trained on a random bootstrap sample of the dataset, and splits are chosen from a random subset of features:

- * **Mechanism:** The final classification is determined by a majority vote of all trees.
- * **Clinical Benefit:** This double randomness (sample and feature bagging) significantly reduces model variance without increasing bias.

Random Forests are exceptionally robust to outliers, handle missing values gracefully, and resist overfitting, making them a top-performing classifier in medical studies (consistently achieving >85% accuracy on liver patient datasets).

4.2 Gradient Boosting Frameworks

Unlike bagging, boosting is a sequential ensemble method where each base learner (typically a weak decision tree) is trained to correct the residual errors made by its predecessors.

XGBoost (Extreme Gradient Boosting):

XGBoost optimizes a regularized objective function that balances predictive performance and model simplicity:

$$\mathcal{L}^{(t)} = \sum_{i=1}^n l(y_i, \hat{y}_i^{(t-1)} + f_t(x_i)) + \Omega(f_t)$$

Where $\Omega(f_t) = \gamma T + \frac{1}{2} \lambda \sum_{j=1}^T w_j^2$ penalizes tree complexity (T leaves and leaf weights w).

Clinical Benefit:

XGBoost is highly efficient, contains built-in handling of missing values, and implements L1/L2 regularization to prevent overfitting on small clinical datasets.

LightGBM (Light Gradient Boosting Machine):

LightGBM grows trees leaf-wise (best-first) rather than level-wise. It uses Gradient-based One-Side Sampling (GOSS) and Exclusive Feature Bundling (EFB) to accelerate training.

Clinical Benefit:

Highly scalable, fast, and performs exceptionally well on massive clinical databases, requiring very low memory overhead.

4.3 Deep Learning:

Multi-Layer Perceptrons (MLP) Deep learning models, such as MLPs, consist of an input layer, multiple hidden layers with non-linear activation functions (e.g., ReLU), and an output layer (sigmoid for binary classification).

$$\text{Layer Output: } a^{(l)} = \sigma(W^{(l)}a^{(l-1)} + b^{(l)})$$

Clinical Benefit:

Deep Neural Networks can learn intricate, high-order combinations of biomarkers without manual feature engineering. Recent papers indicate that DNNs coupled with autoencoders (for feature compression) can achieve accuracies exceeding 92% on large-scale hepatic data. However, they lack direct interpretability, requiring external tools (SHAP) to explain their predictions to medical professionals.

4.4 Model Optimization and Hyperparameter Tuning

To extract maximum performance, models must be tuned systematically. Rather than using arbitrary configurations, the standard pipeline employs:

- * **GridSearchCV:** Performs an exhaustive search over a specified parameter grid (e.g., testing different tree depths, learning rates, and estimator counts).
- * **Stratified K-Fold Cross-Validation:** The training data is split into K folds while maintaining the original class ratio (disease vs. healthy) in each fold.

This ensures that the validation score is representative and protects the model against optimistic bias.

PAGE 5: MEDICAL BIOMARKERS & DATASET CHARACTERISTICS

To design a robust diagnostic system, we must examine the specific datasets and clinical parameters used in hepatology ML.

5.1 Comparative Study of Benchmark Datasets

Academic literature relies heavily on two public datasets. Their structural differences dictate the pre-processing requirements:

1. Indian Liver Patient Dataset (ILPD):
 - **Source:** UCI Machine Learning Repository (collected from Andhra Pradesh, India).
 - **Size:** 583 instances (416 liver disease patients, 167 healthy controls).
 - **Attributes:** 10 (Age, Gender, Total Bilirubin, Direct Bilirubin, Alkaline Phosphotase, Alamine Aminotransferase, Aspartate Aminotransferase, Total Proteins, Albumin, Albumin/Globulin Ratio).
 - **Imbalance:** Strong majority class bias (~71% diseased). Requires SMOTE to prevent classification collapse.
 - **Missing Data:** Contains missing values in the Albumin/Globulin Ratio column, requiring imputation.
2. BUPA Liver Disorders Dataset:
 - **Source:** UCI Repository (created by BUPA Medical Research, UK).
 - **Size:** 345 instances.
 - **Attributes:** 7 (five blood tests, number of half-pint equivalent drinks per day, and a selector field).
 - **Crucial Caveat:** The 7th column (selector) is not a disease label but a train/test split indicator. Using it as a target variable leads to false classification results. The dataset measures liver damage primarily related to heavy alcohol consumption, making it less representative of general liver diseases (like viral hepatitis or MASLD).

5.2 Clinical Explanation of Features

Understanding the medical significance of each blood marker allows for better feature engineering:

LIVER BIOMARKER PROFILE	
Bilirubin (Total & Direct)	Heme breakdown product; elevated levels indicate biliary blockage or jaundice.
Transaminases (ALT/SGPT, AST/SGOT)	Intracellular enzymes; elevated levels represent liver cell injury (necrosis).

Alkaline Phosphatase (ALP)	Bile duct enzyme; elevated levels suggest	
	cholestasis or bone pathologies.	
+-----+		
Serum Proteins (Albumin, Globulin)	Synthesized by the liver; decreased Albumin	
	reflects impaired liver synthesis (cirr.)	
+-----+		

Total Bilirubin (TB) & Direct Bilirubin (DB):

Bilirubin is a yellow-orange pigment formed by the breakdown of senescent red blood cells. The liver conjugates bilirubin to make it water-soluble (Direct Bilirubin) for excretion.

Clinical Significance:

High TB and DB levels indicate that the liver is unable to clear bilirubin, pointing toward cholestasis, hepatitis, or biliary duct obstruction.

Alkaline Phosphatase (ALP):

An enzyme concentrated in the cells lining the biliary ducts, bones, and placenta.

Clinical Significance:

Elevated ALP is a classic marker of cholestasis (sluggish or blocked bile flow) and biliary cirrhosis.

Alamine Aminotransferase (ALT/SGPT) & Aspartate Aminotransferase (AST/SGOT):

These are transaminase enzymes critical for amino acid metabolism. ALT is highly specific to liver tissue, whereas AST is also found in cardiac muscle, skeletal muscle, and kidneys.

Clinical Significance:

When hepatocytes (liver cells) are damaged or die, these enzymes leak into the bloodstream. A high AST/ALT ratio can differentiate alcoholic liver disease (ratio > 2) from viral hepatitis or fatty liver (ratio < 1).

Total Proteins (TP), Albumin (ALB), and the A/G Ratio:

Albumin is the major protein synthesized by the liver, maintaining oncotic pressure and transporting hormones. Globulins are immunoglobulins produced by the immune system.

Clinical Significance:

In chronic liver failure or cirrhosis, the liver's synthetic capacity drops, leading to low Albumin. Because Globulin levels often rise due to immune activation, the Albumin-to-Globulin (A/G) ratio drops significantly, serving as a highly sensitive indicator of chronic liver disease. 5.3 Correlation Analysis of Biomarkers Clinical features are highly correlated. For instance: * Total Bilirubin and Direct Bilirubin typically exhibit a Pearson correlation coefficient (r) of > 0.85, leading to multicollinearity. * AST and ALT also show high correlation (r > 0.75). * Machine learning pipelines can benefit from feature selection or dimensionality reduction (e.g., dropping Direct Bilirubin or using PCA) to prevent model confusion and speed up training.

PAGE 6: SYSTEM ARCHITECTURE & DATA PREPROCESSING PIPELINE

To translate clinical parameters into reliable predictions, the system must implement a strict preprocessing and computational pipeline.

6.1 Data Preprocessing & Missing Value Imputation

Raw medical datasets are often dirty and incomplete.

The system executes the following steps:

- 1. **Handling Missing Values:** In the ILPD dataset, the Albumin_and_Globulin_Ratio column has missing entries. Dropping these rows reduces our limited training set. The system applies Median Imputation (replacing missing values with the median of that column based on the patient's class) to maintain statistical stability without introducing mean-imputation outliers.
- 2. **Categorical Encoding:** The Gender variable (Male/Female) is converted to numeric format via Label Encoding (Male = 1, Female = 0) or One-Hot Encoding.
- 3. **Feature Standardization:** Because algorithms like SVM and KNN compute distances, features with large scales (e.g., Alkaline Phosphatase, which ranges from 60 to >2000) would dominate features with small scales (e.g., Albumin, which ranges from 0.9 to 5.5).

The system applies **Z-score Standardization**:

$$z = (x - \mu) / \sigma$$

6.2 Solving Class Imbalance

The ILPD dataset contains 416 diseased cases and only 167 healthy controls. If trained on this raw distribution, the ML model will develop a strong bias toward predicting liver disease, resulting in very low specificity (failing to identify healthy patients).

- * **SMOTE (Synthetic Minority Over-sampling Technique):**
Synthesizes new, non-overlapping healthy samples along the line segments joining k-nearest neighbors of the minority class.
- * **SMOTE-ENN:**
Combines SMOTE with Edited Nearest Neighbors (ENN). After generating synthetic points, ENN inspects each point's neighbors. If a point is misclassified by its neighbors, it is removed.

This eliminates overlapping boundary points, producing clean, separable decision boundaries.

6.3 Feature Selection & Dimensionality Reduction

To prevent multicollinearity:

- * **Multicollinearity Removal:** Direct Bilirubin is dropped, keeping only Total Bilirubin. This reduces feature redundancy and simplifies the model.
- * **Recursive Feature Elimination (RFE):** Fits a model (e.g., Random Forest) and removes the weakest features one by one, identifying the optimal subset of biomarkers.

6.4 System Architectural Flowchart

The following Mermaid diagram outlines the operational pipeline of the Liver Disease Prediction System:

PAGE 7: CLINICAL INTERPRETABILITY (XAI) & DEPLOYMENT STRATEGY

7.1 The "Black Box" Problem in Healthcare AI

Even if a machine learning model achieves 99% accuracy, clinicians will hesitate to deploy it if they cannot understand why a patient is flagged as high-risk. A diagnosis without a physiological explanation is a liability in medical practice. Explainable AI (XAI) is the key to resolving this "black box" limitation.

7.2 SHAP & LIME for Model Interpretability

To provide full transparency, our system integrates **SHAP (SHapley Additive exPlanations)**, a game-theoretic approach that explains the output of any machine learning model.

Shapley Value Formula:

The Shapley value ϕ_i of feature i represents its average marginal contribution to all possible feature subsets:

$$\phi_i(v) = \sum_{S \subseteq N \setminus \{i\}} \left[\frac{|S|! (|N| - |S| - 1)!}{|N|!} \right] \cdot [v(S \cup \{i\}) - v(S)]$$

- **Local Explanation:** For an individual patient, the system generates a **Force Plot**. This shows exactly how each biomarker pushed the prediction away from the baseline (average prediction). For example, if a patient has a 75% risk of liver disease, the plot will visually show that an ALT level of 120 U/L and a Total Bilirubin of 3.2 mg/dL pushed the risk up, while a high Albumin level of 4.2 g/dL pulled it down.
- **Global Explanation:** The system generates a **Summary Plot** showing the overall feature importances across the entire dataset, helping clinicians validate that the AI is learning legitimate medical associations rather than fitting to noise.

7.3 Technology Stack & API Design

To build a scalable, clinical-grade prediction system, the following modern architecture is recommended:

-----+	+	-----+
FRONTEND UI		BACKEND API
(Next.js / Tailwind)	<==>	(FastAPI / Python)
- Interactive Clinical Form		- Pre-trained Stacking Classifier
- Recharts Risk Gauge		- Fast SHAP Explainer Generator
- SHAP Force Plot Visualization		- Model Registry (MLflow/Joblib)
-----+		-----+

Backend API (Python & FastAPI):

1. **Fast API:** Chosen for its high performance, automatic OpenAPI documentation, and asynchronous capabilities.
 2. **Joblib:** Used to load the pre-trained, cross-validated stacking ensemble model.
- Endpoints:
- POST /predict: Receives JSON patient data, executes preprocessing, runs prediction, and returns the risk probability.
 - POST /explain: Generates the SHAP force plot values for the input patient profile.

Frontend UI (Next.js & Tailwind CSS):

1. A premium, glassmorphic layout using Outfit/Inter typography.
2. Input sliders and forms with clinical validation (e.g., preventing out-of-range inputs).
3. Visualization: Uses Recharts for the risk gauge and SVG-rendered charts for SHAP explanations.

7.4 Verification and Evaluation Metrics

The system's diagnostic capability is verified using five core metrics:

1. **Accuracy:** The ratio of correct predictions to total instances.
2. **Sensitivity / Recall:** The ability of the system to identify diseased patients correctly (crucial to prevent false negatives):

$$\text{Recall} = TP / (TP + FN)$$

3. **Specificity:** The ability to identify healthy patients correctly:

$$\text{Specificity} = TN / (TN + FP)$$

4. **F1-Score:** The harmonic mean of precision and recall:

$$\text{F1-Score} = 2 \cdot (\text{Precision} \cdot \text{Recall}) / (\text{Precision} + \text{Recall})$$

5. **AUC-ROC (Area Under the Receiver Operating Characteristic Curve):** Measures the model's ability to distinguish between classes across all decision thresholds. A clinically viable model should target an AUC-ROC > 0.90.

7.5 Future Directions

- **Multimodal Integration:** Combining chemical liver panel profiles with genomic data or diagnostic text reports to build a unified patient health profile.
- **Federated Learning:** Training models across multiple hospital databases locally to preserve patient privacy while building a robust, highly generalized global classifier.
